TO: Dr. Anthony J. Broccoli
Editor, Journal of Climate
SUBJECT: GFDL ESM2M/ESM2G carbon cycle documentation manuscript

Dear Dr. Broccoli,

Following on from our recently accepted manuscript to *Journal of Climate*, "GFDL's ESM2 global coupled climate-carbon Earth System Models Part I: Physical formulation and baseline simulation characteristics", my co-authors and myself a proud to submit for your consideration the second part of this model documentation, "GFDL's ESM2 global coupled climate-carbon Earth System Models Part II: Carbon system formulation and baseline simulation characteristics" which provides the background biogeochemical description for GFDL's two coupled carbon Earth System Models that are being used as GFDL's contribution in support of the fifth phase of the Coupled Model Intercomparison Project in preparation for the fifth assessment of the Intergovernmental Panel on Climate Change. We are currently revising the companion manuscript describing the physical components based on the editor's and reviewers comments in order to hopefully publish the two contributions as a set. Together, we believe these manuscripts represent a critical contribution to the climate modeling field as they describe a new set of state of the art coupled carbon climate models and explore the role of ocean physical configuration on climate sensitivity.

Thank you very much for your consideration of this manuscript. Please let me know if there is anything I can do to expedite its consideration.

Sincerely,

A handwritten signature in black ink, appearing to read "John Dunne". The signature is fluid and cursive, with a long horizontal stroke at the end.

19 **Abstract**

20 We describe the carbon system formulation and simulation characteristics of two new
21 global coupled carbon-climate Earth System Models, ESM2M and ESM2G. These models
22 demonstrate similar climate fidelity as the Geophysical Fluid Dynamics Laboratory’s previous
23 CM2.1 climate model as described in *Part I* while incorporating explicit and consistent carbon
24 dynamics. The two models differ almost exclusively in the physical ocean component; ESM2M
25 uses Modular Ocean Model version 4.1 with vertical pressure layers while ESM2G uses
26 Generalized Ocean Layer Dynamics with a bulk mixed layer and interior isopycnal layers. On
27 land, both ESMs include a new land model to interactively simulate vegetation distributions and
28 functioning, including carbon cycling among vegetation, soil and atmosphere. In the ocean,
29 both models include new biogeochemical algorithms including phytoplankton functional group
30 dynamics with flexible stoichiometry. Preindustrial simulations are spun up to give stable,
31 realistic carbon cycle mean and variability. Significant differences in simulation characteristics
32 of these two models are described. Due to differences in oceanic ventilation rates (*Part I*)
33 ESM2M has a stronger biological carbon pump but weaker northward implied atmospheric CO₂
34 transport than ESM2G. The major advantages of ESM2G over ESM2M are: improved
35 representation of surface chlorophyll in the Atlantic and Indian Oceans and thermocline
36 nutrients and oxygen in the North Pacific. Additionally, changes in tree mortality parameters in
37 ESM2G produced a more realistic carbon accumulation in vegetation pools. The major
38 advantages of ESM2M over ESM2G are reduced nutrient and oxygen biases in the Southern and
39 Tropical Oceans.

40

41 **Introduction**

42 We describe the carbon system formulation and simulation characteristics of two new
43 global coupled climate-carbon Earth System Models (ESMs; Fung et al., 2000) developed at the
44 National Oceanic and Atmospheric Administration (NOAA) Geophysical Fluid Dynamics
45 Laboratory (GFDL). Like global box models (e.g. Seigenthaler and Sarmiento, 1993; Figure 1A),
46 ESMs represent major carbon reservoirs and fluxes (Figures 1B and 1C). As ESMs are extensions
47 of climate models, they are based on mechanistic geophysical understanding with
48 geographically explicit atmosphere, ocean, land and sea ice dynamics. To physical climate, ESMs
49 add interactive carbon dynamics and associated chemistry and ecology to represent interactions
50 on timescales from minutes to millennia and explore Earth System behavior at both equilibrium
51 and in transient. ESMs resolve coupled climate-carbon responses to diverse anthropogenic
52 perturbations such as fossil fuel emissions, agriculture and forestry, and aerosol chemistry
53 within a single, self-consistent system.

54 Carbon in both the land and ocean has been implicated as having potentially strong
55 responses and feedbacks to anthropogenic forcing. In a climate model with collapsing North
56 Atlantic Overturning (Manabe and Stouffer, 1993), Sarmiento and LeQuere (1996) added simple
57 ocean biogeochemistry to suggest that ocean carbon uptake and biological feedbacks exhibit
58 high sensitivity and uncertainty. Friedlingstein et al. (2003) compared two early ESMs to show
59 that CO₂ feedbacks were highly sensitive to representation of both the Southern Ocean and
60 land vegetation and soil responses. Friedlingstein et al. (2006) compared a suite of early ESMs
61 to suggest that land and ocean carbon responses each accounted for >100 PgC in emissions

62 uncertainty at an atmospheric CO₂ concentration of 700 ppm. Since then, much effort has
63 gone into developing fully coupled ESMs with long term stability in both climate and carbon
64 (e.g. Doney et al., 2006). One fundamental development has been the simulation of climate
65 without flux adjustment (e.g. Delworth et al., 2006; Reichler et al., 2008). Considerable
66 development has also taken place in both ocean biogeochemistry (e.g. Moore et al., 2004) and
67 land carbon (e.g. Thornton et al., 2007) models. Initial comparison of second generation ESMs
68 has shown large variability (e.g. Steinacher et al., 2010). More extensive comparison is
69 expected as part of the Coupled Model Intercomparison Project version 5 (CMIP5; Taylor et al.,
70 2011).

71 Our goal was to develop two ESMs with different ocean vertical coordinate and
72 dynamical/physical core while adhering to the climate fidelity of GFDL's CM2.1 (Delworth et al.,
73 2006). The primary benefit of our approach is to explore the sensitivity of ocean carbon and
74 heat uptake to anthropogenic forcing under fundamentally different frameworks describing
75 ocean dynamics. While the z-coordinate framework holds many benefits, the extreme
76 anisotropy of mixing and advection leads to spurious numerical mixing (Griffies et al., 2000;
77 Ilicak et al., 2012). While the isopycnal framework takes advantage of the relative ease of
78 motion between isopycnal layers, it loses resolution in the unstratified ocean. Comparison
79 between these formulations thus allows assessment of the relative and absolute fidelity of both
80 approaches in representing ocean physics, climate and biogeochemistry.

81 Dunne et al. (accepted; hereafter *Part I*), described the physical climate simulations of
82 both the z-coordinate (ESM2M) and isopycnal-coordinate (ESM2G) models, finding them of

83 similar overall fidelity but having distinct differences. Among these, while ESM2M warms in the
84 interior and thickens the thermocline, ESM2G cools and thins the thermocline. While ESM2M
85 has more thermocline ventilation, ESM2G has more bottom water ventilation. While ESM2M
86 has an overly vigorous El Niño Southern Oscillation, that in ESM2G is rather weak.

87 First we describe the carbon cycle components in these two ESMs. We then discuss the
88 initialization method used to obtain stable climate and carbon states. Finally, we present results
89 from preindustrial control integrations with 1860 radiative forcing and potential vegetation (i.e.
90 no land use) allowed to spin up for over 1000 years and then allowed to run with CO₂
91 interacting freely between the ocean-atmosphere-land system for another 600 years.

92

93 **Model description**

94 The physical components for the ESMs presented here are fully described in *Part I* with
95 only the carbon system components described below.

96 ***Ocean Ecology and Biogeochemistry***

97 The current GFDL ocean biogeochemical and ecological component is Tracers of Ocean
98 Phytoplankton with Allometric Zooplankton code version 2.0 (TOPAZ2). A technical description
99 of TOPAZ version 0 is available in Dunne et al. (2010). TOPAZ version 1 was discussed in Henson
100 et al. (2009). TOPAZ2 includes 30 tracers to describe the cycles of carbon, nitrogen, phosphorus,
101 silicon, iron, oxygen, alkalinity and lithogenic material as well as surface sediment calcite (Dunne
102 et al., submitted). TOPAZ2 considers three explicit phytoplankton groups ('small', 'large', and

103 diazotrophic) that utilize a modified growth physiology after Geider et al. (1997) with Eppley
104 (1972) temperature functionality and iron co-limitation with luxury uptake after Sunda and
105 Huntsman (1997). 'Small' represent mostly prokaryotic picoplankton and nanoplankton, while
106 'large' represents diatoms, greens and other large eukaryotes. Diazotrophs represent
107 facultative nitrogen fixers with nitrogen fixation inhibited by nitrate (NO_3), ammonia (NH_4) and
108 oxygen (O_2). $\text{CO}_2:\text{NO}_3:\text{O}_2$ stoichiometry is 106:16:150 after Anderson (1995). N:P is based on
109 optimal allocation after Klausmeier et al. (2004).

110 Phytoplankton loss and production of sinking detritus utilize the size-based relationship
111 of Dunne et al. (2005) with mineral-driven penetration of sinking detritus (Klaas and Archer,
112 2002; Dunne et al., 2007). TOPAZ2 diagnoses plankton mineral formation of opal, calcite, and
113 aragonite. TOPAZ2 includes seasonal time scale dissolved organic material and heterotrophic
114 biomass with fixed N:P and multiannual dissolved organic material with variable N:P. Gas
115 exchange of O_2 and CO_2 follows Najjar and Orr (1998). Nitrification is inhibited by light after
116 Ward et al. (1982). TOPAZ2 includes second-order iron scavenging with ligand kinetics,
117 lithogenic particle scavenging, water column denitrification under suboxia, and sediment
118 denitrification after Middelburg et al. (1996). In the absence of both NO_3 and O_2 , a respiration
119 deficit is accumulated as negative O_2 . TOPAZ2 includes external inputs of atmospheric nitrogen
120 deposition (Horowitz et al., 2003), lithogenic dust and soluble iron (Fan et al., 2006), river
121 nitrogen (Seitzinger et al., 2005), and river inputs of dissolved inorganic carbon, alkalinity and
122 lithogenic material set to balance Holocene burial of calcite and lithogenic material (Dunne et
123 al., 2007).

124 ***Land Vegetation and Carbon Cycle***

125 The current GFDL land model (LM3) represents vegetation as 5 dynamically competing
126 vegetation types: deciduous, coniferous, and tropical trees and warm and cold grasses. The five
127 vegetation types are combinations of three characteristics: C3 versus C4 leaf physiology, leaf
128 longevity (i.e. temperate cold-deciduous, tropical broadleaf, and coniferous evergreen), and
129 allocation ratios among stems, roots, and leaves (i.e. trees versus grass). The tropical tree type
130 can behave as evergreen or deciduous depending on the drought conditions. Vegetation height
131 varies as a function of plant biomass across a continuum from shrubs through trees. All
132 vegetation types have five carbon pools: leaves, fine roots, sapwood, heartwood, and labile. The
133 sizes of all pools are modified daily through a set of allocation rules based on the amount of
134 carbon accumulated in the biophysics module governing exchanges of water and CO₂ on fast
135 time scales (30 minutes). LM3's photosynthesis is based on Farquhar et al. (1980) and Collatz et
136 al. (1991, 1992). The relationship between stomatal conductance and net photosynthesis is
137 based on Leuning (1995).

138 LM3 simulates changes in the vegetation carbon pools through phenology (e.g. leaf drop
139 and emergence), natural mortality, and fire. Carbon loss from vegetation pools is deposited into
140 two soil carbon pools that decompose at seasonal and multi-year timescales with the rates
141 dependent on the amount of carbon, temperature, and water. Annual fire loss is proportional
142 to fuel available and number of drought months. To ameliorate temperate biomass biases seen
143 in initial ESM2M runs, ESM2G mortality was increased for evergreen coniferous trees from
144 0.015 a⁻¹ to 0.0275 a⁻¹ and for temperate deciduous trees from 0.015 a⁻¹ to 0.025 a⁻¹ while their
145 branch-wood turnover rate was doubled.

146 One unique feature of LM3 is land-use heterogeneity in which each grid-cell is described
147 as a combination of four land-use categories (tiles): undisturbed lands (i.e. “primary” or
148 “potential”), croplands, pastures, and lands either previously harvested or used in agriculture
149 (i.e. “secondary”). Each tile has its own carbon and physical state, above and belowground. In
150 the absence of human disturbances, all grid-cells on land represent potential vegetation. These
151 simulations were performed for the potential state of the vegetation and should more correctly
152 be considered ‘pre-human’ rather than ‘preindustrial’ due to their lack of incorporation of land
153 use history up to 1860. Nonetheless, for this work we retain the ‘preindustrial’ moniker for
154 consistency with previous work.

155 ***Atmospheric CO₂***

156 Atmospheric CO₂ was treated as an explicit prognostic tracer exchanging CO₂ with land
157 surface and ocean surface every 30 min and 2hr, respectively. For the initial phase of the long
158 spin up (~1000 years) spin-up described here, this atmospheric CO₂ tracer was subjected to
159 global, linear restoring to 286 ppm dry volume mixing ratio throughout the atmosphere with a
160 restoring timescale of 1 year. This restoring approach was found to provide considerable
161 advantages over the more direct, surface concentration override approach as it enabled the
162 development of realistic diurnal and seasonal timescale CO₂ variability over the land which in
163 turn influences plant growth and thus the land carbon inventory. Furthermore, it eliminated
164 atmospheric CO₂ drift in the later phase of the spin up for both ‘restored’ CO₂ control and
165 perturbed concentration scenarios, as well as scenarios with ‘free’ CO₂ (i.e. atmosphere
166 exchanges CO₂ with ocean and land without any restoring and is free to evolve in 1860 control
167 and emissions perturbation scenarios rather than being ‘restored’ to a pre-set value). The

168 model global average atmospheric CO₂ concentration is also used by the radiation code for the
169 radiation calculation.

170 ***Initialization***

171 To obtain the 1860 initial conditions for the climate model's control integration, a
172 method similar to that described by Stouffer et al. (2004) is used. The model is initialized with
173 present day conditions for ocean temperature (Locarnini et al., 2006) and salinity (Antonov et
174 al., 2006) from the World Ocean Atlas 2005 in netCDF (Collier and Durack, 2006) and the ocean
175 and sea ice run for a single year forced by atmospheric conditions from a CM2.1 control run.
176 Biogeochemical tracers were initialized from observations from the World Ocean Atlas 2005 for
177 nitrate, phosphate, silicate and oxygen (Garcia et al., 2006a; 2006b) and GLObal Ocean Data
178 Analysis Project (GLODAP; Key et al., 2004) for alkalinity and dissolved inorganic carbon after
179 subtracting off their anthropogenic carbon estimate. Sediment calcite is derived assuming
180 steady state bottom water conditions and fluxes after Dunne et al. (submitted). All 1860
181 radiative forcings were included simultaneously at spin-up. The model was time integrated over
182 1000 model years in order to achieve a quasi-equilibrium defined by the net atmosphere-land
183 and atmosphere-ocean fluxes being less than 0.1 PgC a⁻¹ on the long term average. From this
184 initial state, the 1860 control integrations and perturbation scenarios are begun. The land
185 model was initialized off-line with CM2.1 climate forcing to obtain initial distribution of
186 vegetation and soil carbon pools. After 500 hundred years, the last 50 years was used for offline
187 soil equilibration after Shevliakova et al (2009) and the soil values reset.

188 **Results**

189 ***Initial Carbon Cycle Drift***

190 While our land carbon and sediment calcite components undergo offline initialization to
191 equilibrium, our ocean components require online equilibration in order to achieve our long
192 term 0.1 PgC a^{-1} quasi-equilibrium goal. Initial ALK and DIC inventory differences are due to
193 differences in total ocean volume (ESM2G has 0.5% more volume than ESM2M) with ESM2M's
194 relatively smooth bathymetry limited to 5500 m while ESM2G extends to 6000 m. Upon
195 initialization with preindustrial dissolved inorganic carbon (DIC) and present day alkalinity (ALK)
196 and nutrient distributions, both ESMs exhibit an initial pause before and then take up additional
197 CO_2 over the first few centuries before coming into equilibrium (Figure 2A and B). The drift in
198 ESM2G starts off strongly and takes up about 10 Pg more carbon than ESM2M, but also comes
199 into equilibrium more quickly. Both models have significant inter-annual variability, with that in
200 ESM2G being of longer period than ESM2M.

201 The rapid uptake of CO_2 in both these models over the first 300 years and long term DIC
202 inventory response relates to a complex interplay of factors including temperature drift,
203 accumulation of remineralized DIC in the tropics, loss of DIC in the deep Southern Ocean, and
204 long term equilibration of the calcite and nitrogen cycles. Because these models have
205 additional sources of carbon and ALK from rivers as well as sources and sinks of calcite from the
206 interaction with surface sediments, the ocean DIC inventory (Figure 2C) does not follow the
207 integrated gas exchange flux (Figure 2B) but rather decreases initially in both models before
208 stabilizing and then decreasing again in ESM2M versus slightly increasing before stabilizing and
209 then decreasing again in ESM2G. This differing long-term behavior between the two models,

210 also apparent in the ALK inventory (Figure 2D), is a result of the multi-millennial timescales
211 associated with the changing lysoclines as the models drift away from initial conditions and the
212 sediment seeks a new equilibrium. The ocean nitrogen inventory in these models (Figure 2E)
213 also undergoes a long term drift due to the imbalance between nitrogen supply from N₂
214 fixation, rivers, and atmospheric deposition versus loss from water column and sediment
215 denitrification, initially increasing, and then decreasing. As we describe below, this drift is due
216 to the common over-expression of pelagic suboxia in this class of models (Najjar et al., 2007).

217 ***Surface Ocean Biogeochemistry***

218 ESM2M and ESM2G share similar overall surface biogeochemical fidelity, but also
219 contrast in important ways. Surface observations are shown in Figure 3 for nitrate (NO₃; Garcia
220 et al., 2010b; Figure 3A), log chlorophyll (log(Chl); Figure 3D), the oceanic minus atmospheric
221 partial pressure of CO₂ ($\Delta p\text{CO}_2$; Takahashi et al., 2009; Figure 3G), and phosphate (PO₄; Garcia et
222 al., 2010b; Figure 3J) are shown along with the corresponding model values in ESM2M (center;
223 Figures 3B, E, H, and K) and ESM2G (right; Figures 3C, F, I, and L). While both models capture
224 most regional variability in surface NO₃ ($r^2 = 0.87$ for ESM2M and $r^2 = 0.91$ for ESM2G), ESM2M
225 has a surplus compared to observations of 1.6 μM compared to the observed average of 5.1 μM
226 70°S-70°N, most notably in the Equatorial Pacific upwelling region, the Subpolar Front of the
227 Southern Ocean near 40°S, and the Subpolar North Atlantic. ESM2G, in contrast, has a muted
228 surplus in the Subpolar Front of the Southern Ocean near 40°S and minimal global scale bias (-
229 0.062 μM). Both models underestimate surface NO₃ in the Subpolar North Pacific, ESM2G more
230 severely.

231 ESM2M and ESM2G capture slightly more than half of log(Chl) spatial variability ($r^2 =$
232 0.54 for ESM2M; $r^2 = 0.52$ for ESM2G; Figures 3D-F). While neither model captures the high
233 values in the north polar, coastal upwelling, and shelf regions, both models capture the
234 transitions between oligotrophic subtropical gyres to mesotrophic, high nitrate regions. While
235 much of these biases are attributable to the atmosphere, ESM2M better represents the tropical
236 West Pacific, while ESM2G better represents the tropical Atlantic and Indian Oceans and
237 subpolar regions of all oceans. We attribute these differences in surface NO_3 and Chl fidelity to
238 differences in mixed layer dynamics (*Part I*) with ESM2G's capacity to represent shallow mixed
239 layers allows phytoplankton maintaining high growth rates with lower chlorophyll than ESM2M.
240 Strong shallow biases in minimum Southern Ocean mixed layer depths in both models (*Part I*)
241 lead to locally low biases in surface NO_3 (ESM2G more severely than ESM2M) and high bias in
242 Chl (ESM2M more severely than ESM2G).

243 Both models capture slightly more than half of spatial ΔpCO_2 variability ($r^2 = 0.56$ for
244 ESM2M and $r^2 = 0.55$ for ESM2G; Figures 3G-I). The primary bias patterns include over
245 expression of high ΔpCO_2 in the northerly and westward expressions of Equatorial Pacific
246 upwelling, more so for ESM2G than ESM2M. ΔpCO_2 in both models is too low in the Northwest
247 Pacific near 40°N , particularly in ESM2G, and too high in the Southern Ocean, particularly east
248 of Australia and Argentina. While the global patterns in PO_4 (Figures 3J-L) bear much similarity
249 with observations ($r^2 = 0.87$ for both models), ESM2M has a significant low bias in PO_4 (-0.087
250 μM) whereas ESM2G does not ($0.0063 \mu\text{M}$), opposite from their relative NO_3 biases.

251 ***Interior Ocean Biogeochemistry***

252 Comparisons of biogeochemical distributions in the ocean interior highlight the limits of
253 these models' abilities to represent large scale ventilation patterns. Observations at 500 m are
254 shown in Figure 4 for dissolved oxygen (O_2 ; Garcia et al., 2010a; Figure 4A), phosphate (PO_4 ;
255 Figure 4D) and nitrate (NO_3 ; Figure 4G) along with the corresponding values in ESM2M (center;
256 Figures 4B, E, and H) and ESM2G (right; Figure 4C, F, and I). While ESM2M reproduces 72% the
257 overall interior O_2 regional variability, it is overly ventilated in both the North Pacific and south
258 of $50^\circ S$ and lacks ventilation of the Eastern Equatorial Pacific and Atlantic (Figure 4B). While
259 ESM2G represents the lack of oxygen ventilation in the North Pacific much better than ESM2M,
260 ESM2G reproduces slightly less (69%) of the variability overall as it exacerbates the ESM2M bias
261 of low ventilation of the tropical and southern subtropical oceans and Southern Ocean north of
262 $60^\circ S$. In addition, ESM2G is overly ventilated south of $60^\circ S$. These patterns are mirrored in the
263 PO_4 patterns at 500 m (Figures 4D-F). Overall, ESM2M has an extremely low overall bias in O_2
264 and PO_4 at 500 m ($-5.2 \mu M$, and $0.005 \mu M$, respectively), while ESM2G has a much larger
265 negative bias in O_2 ($-32 \mu M$) and positive bias in PO_4 ($0.31 \mu M$). Combined with their good
266 surface representation (Figures 3J-L), we infer these O_2 biases as due to under-ventilation
267 leading to excess accumulation of remineralization. Comparison of NO_3 at 500 m (Figures 4G-I),
268 highlights the severe implications of these ventilation biases for the nitrogen cycle as over-
269 expression of suboxia leads to excess denitrification and subsequent NO_3 deficiency in the
270 eastern tropical Pacific of ESM2M and even more so in ESM2G. This leads to both significant
271 global NO_3 drift (Figure 2E) and to ESM2G's relative surplus in surface PO_4 (Figure 3L).

272 Model fidelity for both Dissolved Inorganic Carbon (DIC) and excess alkalinity ($ALK_{EXCESS} =$
273 $ALK - DIC$; an approximation of the ocean buffering potential with respect to addition of CO_2 and

274 other acid) is demonstrated in Figure 5 through regional comparison of observed and modeled
275 profiles. In the North Atlantic (Figure 5A), distributions of DIC and ALK_{EXCESS} have intermediate
276 values throughout the water column, with ESM2G DIC values slightly elevated above 3000 m,
277 and ESM2M DIC values slightly depressed below 700 m. ALK_{EXCESS} in both models, however,
278 agrees well with observations in the upper water column but is slightly elevated below 700 m.
279 In all tropical areas (Figure 5B), both models have elevated DIC at the base of the thermocline
280 down to 2000 m consistent with their elevated phosphate and over expression of suboxia in the
281 East Pacific (Figure 4), ESM2G more strongly and more into the thermocline than ESM2M.
282 ALK_{EXCESS} is correspondingly depressed, though the observed structure is well-preserved. In the
283 North Pacific (Figure 5C), ESM2G reproduces the DIC profile down to 700 m but has strongly
284 depressed values below, while ESM2M underestimates DIC down to 2000 m with both models
285 overestimating ALK_{EXCESS} through much of the water column. The differences in these deep
286 patterns is due to the much higher Antarctic Bottom Water transport and lower ideal age
287 distribution in ESM2G than ESM2M discussed in *Part I*. In the Southern Ocean (Figure 5D), DIC
288 patterns similarly reflect these models' differing ventilation, with ESM2M reproducing the DIC
289 profile extremely well down to 1200 m but having depressed values below, while ESM2G has
290 elevated values in the 300-1400 m range and depressed values below. Both models exhibit
291 slightly depressed ALK_{EXCESS} in this region above 1200 m and elevated values below.

292 ***Marine Ecosystem Functioning***

293 The similar atmospheric coupling and identical biogeochemical algorithms but differing
294 thermocline ventilation in these two models (*Part I*) results in roughly scaled marine ecological

295 functioning. Both models broadly center primary production on the equator with mid-latitude
296 secondary maxima (Figures 6A-B) due to the combination of nutrient supply and equator-to-
297 pole gradient in light and temperature. As a result of its more vigorous thermocline ventilation,
298 ESM2M has higher total primary production than ESM2G in most ocean areas (Figure 6C).
299 Patterns in large phytoplankton production (Figures 6D-F) are similar, except that the high
300 productivity regions are more locally restricted to the site of ventilation. Exceptions to this
301 general pattern include ESM2G's: 1) Southern Ocean high productivity ribbons shifted slightly
302 southward, 2) a smaller Western Equatorial Pacific warm pool (*Part I*), and 3) California Current
303 upwelling drawing from a shallower nutricline (Figure 5C). Nitrogen fixation patterns (Figures
304 6G-I) highlight the differing N:P stoichiometry in these models (Figure 4) with ESM2G (Figure
305 6G) having much higher nitrogen fixation in the North Pacific than ESM2M (Figure 6H) and 19%
306 higher nitrogen fixation globally (ESM2G - 173 TgN a⁻¹; ESM2M - 146 TgN a⁻¹).

307 Comparison of zonally integrated metrics of the organic carbon pump (Figure 7A)
308 illustrates both similarities and differences between ESM2M (solid) and ESM2G (dash). In both
309 models, sinking particle export (black) follows large phytoplankton production (green) and NO₃-
310 based production (light blue). Net community production (total primary production minus
311 respiration; blue) and net phytoplankton production (total primary production minus grazing;
312 red) exhibit more focused maxima in the high productivity regions. While the patterns of the
313 two models are similar due to their similar atmospheric forcing, the ESM2M organic carbon
314 pump is generally stronger than the ESM2G pump due to ESM2M's more vigorous thermocline
315 ventilation (*Part I*). The similar biogeochemical response to atmospheric forcing is highlighted
316 in net phytoplankton production (red) as upwelling-driven biomass accumulation and lateral

317 transport near the equator and convection-driven vertical transport at mid-latitudes. South of
318 40°S, while NO₃-based production (light blue) is nearly identical in these models, net
319 community production (blue) and particle export (black) are considerably lower in ESM2G than
320 ESM2M. This differing behavior in the Southern Ocean is due to their differences in depth-
321 resolution of light-inhibited nitrification. While ESM2M always has 10 m euphotic zone
322 resolution, ESM2G changes euphotic zone resolution based on stratification. Particularly in the
323 Southern Ocean, ESM2G layers directly below the mixed layer can thicken enough to relieve
324 light inhibition of nitrification and drive down ammonia.

325 The mineral pumps (Figure 7B) each highlight different controls dominating in different
326 regions. The silicon export (green) dominates in high productivity areas, the calcite pump (blue)
327 in the high temperature and saturation state tropics, the aragonite pump (black) in high
328 productivity tropical areas, and the lithogenic pump (red) focused in the northern hemisphere.
329 The similarity of the lithogenic pump between the two models is due to the fact that each was
330 given the same external supply from atmospheric deposition and river runoff. Note that while
331 the silicon pump is the strongest in terms of mass, all mineral pumps are important to the deep
332 organic carbon cycle due to the relative efficiency in mineral protection efficiency assumed for
333 calcite (0.070), aragonite (0.070), and lithogenic (0.065) mineral relative to silicon (0.026; Klaas
334 and Archer, 2002), and deep dissolution scales assumed for calcite and lithogenic mineral.

335 ***Land Vegetation and Carbon***

336 Both ESMS dynamically simulate vegetation characteristics as a function of climate and
337 atmospheric CO₂ concentration. To assess ESM2M and ESM2G fidelity with respect to land

338 dynamics, we compare three bulk characteristics critical to land-climate interactions: The
339 distribution of vegetation types, total carbon storage, and the seasonal extremes of partitioning
340 among different pools into leaves. We have combined information on the ESMs simulated
341 vegetation type distribution with other vegetation characteristics (e.g. biomass, seasonality) to
342 classify each of the land model grid-cells into one of the ten Aggregated Olson Ecotypes.
343 Overall Ecotypes distributions (Olson et al., 1985) in both ESM2M (Figure 8B) and ESM2G
344 (Figure 8C) compare well to observational estimates (Gibbs, 2006; Figure 8A) in representing the
345 general distinction between warm grassland, tropical forest, cold grassland, hot sandy desert,
346 deciduous forest, savanna, and coniferous forest, while tundra is under-represented in both
347 models and permanently iced areas such as Greenland and Antarctica are specified. The
348 models both over extend the areal coverage of tropical forest in South America and Africa at the
349 expense of savanna, and over extend the areal coverage of hot sandy desert in Africa and South
350 Asia at the expense of warm grassland. The models also exaggerate overestimate the westward
351 extent of deciduous forest in North America and East Asia. Also in comparison to observational
352 estimates (Gibbs, 2006; Figure 8D), both models (Figures 8E, F) overestimate both tropical and
353 deciduous forest biomass, while due to the tuning differences, coniferous biomass is better
354 represented in ESM2G than ESM2M.

355 As an essential ingredient for hydrological, radiative and carbon exchanges in the ESMs,
356 we compare the ESM partitioning of biomass to leaves against the Normalized Difference
357 Vegetation Index (NDVI) to evaluate whether the models make the correct amount of leaves at
358 their seasonal extremes. Comparisons of NDVI in both models against the Moderate Resolution
359 Imaging Spectroradiometer (MODIS) satellite (Figures 8G-L) illustrates strong agreement as

360 expected from the spectral calibration used in LM3 (Milly et al., submitted; *Part I*). The
361 climatological maximum comparison (Figures 8G-I) illustrates that the extent of permanent
362 deserts and semiarid regions is under represented in these models. This is because the low
363 precipitation extremes are not as extreme as in the satellite estimate. The climatological
364 minimum comparison (Figures 8J-L) illustrates the excellent observational agreement achieved
365 with these models in both the Northern Hemisphere snow line extent and transition between
366 coniferous and deciduous forests. However, the models appear to have overly high minimum
367 NDVI in tropical forest indicating a possible bias in lack of vegetation sensitivity to climate in
368 these regions.

369 Given that both ESMs share the same atmosphere and land model except for tree
370 mortality parameters, it is not surprising that the two models share nearly identical features.
371 Three main issues complicate evaluation of vegetation characteristics in these simulations. First,
372 most land vegetation and soil datasets are for present day conditions and include a substantial
373 footprint of past human activities. By design, the control experiments are performed for the
374 potential, preindustrial state. Second, most global datasets are derived from point
375 measurements extrapolated in space - often a product of complicated models themselves - with
376 high uncertainty. Third, as with many categorical variables, the challenge in evaluating a
377 modeled vegetation type distribution is that there is no exact correspondence between types of
378 vegetation used in the models and different vegetation classifications used to describe the state
379 of the land. We choose Olson Major World Ecosystem Types dataset for such comparison
380 because it was designed to reflect carbon content of different ecotypes as well degree of human
381 management of those ecosystems.

382 ***Atmospheric CO₂ Cycling***

383 Combined land and ocean CO₂ fluxes into the atmosphere are shown in Figure 9. In the
384 long term mean (Figures 9A, B) only ocean fluxes are apparent as land biomass is near
385 equilibrium on the centennial scale. While ESM2M and ESM2G share similar overall CO₂ flux
386 patterns, ESM2M has its strongest in-gassing north of Norway whereas that in ESM2G occurs in
387 the Sea of Japan and Kuroshio Extension. ESM2M also shows strong in-gassing along the coast
388 of Antarctica while ESM2G does not. Focusing on the monthly CO₂ flux variability (Figures 9C,
389 D) nearly completely obscures the ocean due to the much higher land signal, with both models
390 showing nearly identical patterns of intensely high fluxes in the tropical South American and
391 African forests and savannas, and secondary zones of flux in tropical Asia, Eastern North
392 America and Western Europe. As expected due to the primary driver of land variability fluxes by
393 precipitation, the partitioning of variability between seasonal versus inter-annual modes of flux
394 (Figures 9E, F) shows a strong dominance of seasonal variability except for the Equatorial Pacific
395 and Indian Oceans as a consequence of the El Niño-Southern Oscillation (ENSO), especially for
396 ESM2M where the ENSO signal extends to the Central Pacific, Indian and Atlantic Oceans.
397 Additionally, ESM2G shows a strong inter-annual signal in the Southern Ocean while inter-
398 annual signals in ESM2M for this region are moderate. ESM2G also shows a more inter-annual
399 component in the Subpolar North Pacific. The local factors driving this variability are explored
400 via the monthly air-land/sea CO₂ flux (F_{CO_2}) correlation with monthly surface temperature (T_{surf})
401 in Figures 9G, H. Strong positive F_{CO_2} - T_{surf} correlations are seen throughout the land but most
402 particularly in South America, Australia and Southeast areas of Asia, Africa, and the United
403 States as a function of the seasonal cycle in irradiance. In the ocean, these positive correlations

404 are restricted somewhat to the subtropics and Ross and Weddell Sea regions where seasonal
405 heating drive solubility-induced fluxes, whereas negative correlations are seen in the tropical
406 and Southern Ocean upwelling areas where remineralized CO₂ drives out-gassing during
407 upwelling of colder subsurface waters. This latter response is seen more prominently in ESM2G
408 than ESM2M due to its stronger pycnocline.

409 Comparison of time-averaged, zonally integrated, preindustrial air-sea fluxes (Figure
410 10A) of heat downward (PW deg⁻¹ into the ocean; dash) and CO₂ upward (PgC deg⁻¹ a⁻¹; solid)
411 and implied ocean transport (Figure 10B) of heat northward (PW; dash) and CO₂ southward (PgC
412 deg⁻¹ a⁻¹; solid) serves to highlight both the differing dynamics controlling heat versus CO₂ fluxes
413 as well as the differences between ESM2M and ESM2G. Relative to heat, CO₂ flux is strong
414 south of 45°S, and meridionally broad in the tropics. As the Southern Ocean release is roughly
415 compensated by uptake south of 15°S, the tropical release is largely balanced northern mid-
416 latitude uptake. This divergence of CO₂ from heat is highlighted in the implied atmospheric CO₂
417 transport being northward at all latitudes north of 60°S whereas the implied ocean heat
418 transport is southward south of the equator (Figure 10B). While the two models have very
419 similar fluxes and transport for heat (ESM2G's northward heat transport being only slightly
420 stronger), ESM2G has a 28% stronger maximum CO₂ transport (0.97 PgC a⁻¹) than ESM2M (0.76
421 PgC a⁻¹) resulting from their differing extents of thermocline ventilation discussed in *Part I*. In
422 ESM2M, CO₂ locally remineralized in the subsurface tends to ventilate back to the atmosphere
423 during winter convection at northern mid-latitudes while ESM2G maintains a stronger biological
424 pump and more uptake at sub-polar latitudes.

425 ***Atmospheric CO₂ Variability***

426 The atmospheric signatures of regional land and ocean CO₂ fluxes are presented in
427 Figure 11. At the regional scale, surface atmospheric CO₂ anomalies from the global mean
428 (Figures 11A, B) are driven at the regional scale by the dominance of land variability over ocean
429 variability (Figure 9) and exhibit broad maxima centered on the productive land areas that
430 spread over the marine areas particularly in the tropics. These features are a consequence of
431 the well-characterized atmospheric CO₂ rectification effect (Denning et al., 1995) such that at
432 night when the boundary layer is thin, the land undergoes net respiration and CO₂ increases
433 dramatically, while during the day when the land undergoes photosynthesis, the boundary layer
434 thickens as the land heats and CO₂ concentrations decrease to a lesser degree. At the global
435 scale, these anomalies also demonstrate a general marine gradient of decreasing CO₂ from
436 south to north as a consequence of the general southward transport of CO₂ in the ocean (Figure
437 10). Temporal changes in global mean surface CO₂ anomalies are highly correlated with
438 temporal changes at regional scales (Figures 11A, B) except for directly above the regions of
439 high land productivity. Because of this globally synoptic behavior, local CO₂ variability in such
440 distant places as Antarctica (black in Figures 11E, F) and Greenland (blue in Figures 11E, F) is
441 largely co-incident ($r^2=0.81$ for ESM2M and $r^2=0.84$ in ESM2G) with concentrations at Antarctica
442 approximately 1.2 ppm higher than at Greenland in ESM2M and 1.3 ppm higher in ESM2G.

443 We compare ESM2M and ESM2G with observations of the amplitude of the marine
444 seasonal CO₂ cycle (Figure 12) to demonstrate the relative dampening of the latitudinal signal
445 long recognized in the atmospheric CO₂ cycle (Fung et al., 1987), with ESM2G suffering slightly

446 more so from this bias than ESM2M due to ESM2G's relatively strong seasonal cycle in the
447 tropics (*Part I*, Figure 7 therein). The cause of the damped meridional gradient is twofold: 1)
448 under predicting the strength of the seasonal cycle in the northern boreal forests and 2) an
449 overly enhanced seasonal cycle in the Amazon. In northern boreal regions, our models initiate
450 CO₂ drawdown approximately one month earlier than observations and return CO₂ to higher,
451 winter values approximately two months early. While our model underestimates maximum
452 NDVI in Siberian forests (Figures 8J-L), our net primary productivity cycle matches that in
453 satellite based estimates (Randerson et al., 1997; not shown), leading us to suspect the
454 underlying net ecosystem production bias to be rather in the seasonality of respiration. The
455 Amazon bias is due to a combination of the overall low Amazon precipitation, relative
456 intensification of length of the dry season, lack of seasonally intense cloud cover, and related
457 soil hydrology biases common to this class of model (*Part I*, Figure 6 therein). These factors
458 result in a modeled Amazonian seasonal CO₂ flux cycle synchronous with the African and
459 Oceania rainforests giving strong CO₂ seasonality extending to the South Pole with net
460 community production driven by precipitation - whereas in observations, a combination of
461 intense cloud cover during the high precipitation season and a lack of water stress at other
462 times results in an Amazonian cycle of opposing phase counteracting the CO₂ signature of the
463 seasonal cycle in the other rainforests.

464 To further quantify atmospheric CO₂ variability, we show as insets in Figure 12 the
465 temporal variability spectrum at the long term Barrow, Alaska, Mauna Loa, and South Pole
466 monitoring stations (detrended; black) compared to ESM2M (red) and ESM2G (green). At high
467 northern latitudes (e.g. Barrow), both models underestimate the annual cycle and sub-annual

468 cycle, but have approximately correct inter-annual variability. At mid-northern latitudes (e.g.
469 Mauna Loa), both models overestimate inter-annual variability (ESM2M more so than ESM2G)
470 and underestimate the seasonal cycle. In the southern hemisphere, both models over estimate
471 variability at both annual and inter-annual time-scales, with ESM2M exhibiting more bias on
472 interannual timescales, and ESM2G exhibiting more bias on annual timescales as both models
473 degas CO₂ from the Southern Ocean in the Austral Summer. This signal is stronger in ESM2G
474 than ESM2M, consistent with its larger warm sea surface temperature bias in the Southern
475 Ocean described in *Part I*.

476 ***Overall Land and Ocean Biosphere Representation in GFDL's ESM2 Class of Models***

477 Overall, the models demonstrate the ability to represent a wide range of coupling
478 between climate and the carbon cycle. Having described all of the various components of these
479 models, we now turn back to the comparison of carbon inventory and flux estimates in Figure 1.
480 Both models demonstrate excellent agreement with previous estimates in terms of the
481 partitioning of carbon between the various reservoirs, though the land vegetation is quite a bit
482 higher and the ocean biota quite a bit lower than those in the observational synthesis and box
483 model analysis of Siegenthaler and Sarmiento (1993) which is used as a quasi-consensus
484 estimate used in the IPCC Fourth Assessment (Randall et al., 2007). There remains a great deal
485 of uncertainty in these estimates, however. While the Sabine et al. (2004) land gross primary
486 production estimate (120 PgC a⁻¹) given in Figure 1 is higher than the original Siegenthaler and
487 Sarmiento (1993) estimate (100 PgC a⁻¹) and similar to the Beer et al. (2010) estimate of 123
488 PgC a⁻¹, it is well below the latest best guess of 150–175 PgC a⁻¹ from the recent observational

489 estimates (Welp et al., 2011). Both ESM2M (141 PgC a⁻¹) and ESM2G (143 PgC a⁻¹) estimates are
490 between these two studies. The global biomass in both models (1044 PgC in ESM2M and 838
491 PgC in ESM2G) compares well to preindustrial estimates of 924 – 1080 PgC (Bazilevich and
492 Rodin, 1971; Adams et al., 1990). Note also that the Siegenthaler and Sarmiento (1993)
493 biomass is for preindustrial (~1850s) which incorporates significant historical land use and is
494 expected to be lower than preindustrial estimates.

495 Ocean primary productivity is higher than the Siegenthaler and Sarmiento (1993) value
496 (50 PgC a⁻¹) in both ESM2M (82 PgC a⁻¹) and ESM2G (68 PgC a⁻¹), and at the upper end of the
497 range of global productivity estimates (36-78 PgC a⁻¹) given in the comparative analysis of Carr
498 et al. (2006) and much higher than the model range given in Steinacher et al. (2010; 24-49 PgC
499 a⁻¹). However, ESM2M (8.0 PgC a⁻¹) and ESM2G (5.4 PgC a⁻¹) are within the range of modeled
500 particulate organic carbon export (5.0-9.1 PgC a⁻¹) in Steinacher et al. (2010), indicating that the
501 primary production differences are largely a function of differing recycling efficiency between
502 these studies. We have split the ESM2M and ESM2G carbon export across 100 m in Figure 1
503 into three terms: dissolved transport which is much smaller than in Siegenthaler and Sarmiento
504 (1993); sinking particulate organic carbon export (bold arrow) which is higher than Siegenthaler
505 and Sarmiento for ESM2M, but of similar magnitude in ESM2G; and combined organic particle
506 (phytoplankton, zooplankton and bacteria) transport and aragonite and calcite sinking.
507 Combined, these export fluxes give an inferred ventilation of the upper 100 m in ESM2M (98
508 PgC a⁻¹) in excellent agreement with Siegenthaler and Sarmiento (1993; 100 PgC a⁻¹) while that
509 in ESM2G (80 PgC a⁻¹) is moderately lower. Note that since these ESMs do not include an
510 explicit representation of organic carbon cycling in rivers, our net atmospheric flux into land is

511 zero, and the river runoff flux of DIC and ALK is specified with a 1:2 ratio to balance calcite burial
512 at steady state. This steady state is yet unachieved in our control runs as ESM2M with 642 PgC
513 in surface sediment calcite is gaining 0.05 PgC a^{-1} and ESM2G with 469 PgC in surface sediment
514 calcite is gaining 0.12 PgC a^{-1} . Assessment of the sensitivity of the sediment calcite inventory to
515 ocean acidification will thus require careful attention to the behavior of the control runs for
516 comparison.

517

518 **Conclusions**

519 Representation of the carbon cycle in GFDL's climate models has exposed a wide range
520 of sensitivities beyond those normally focused upon in analysis of climate. As discussed above,
521 many of the biases relative to observationally based estimates are common to both models. On
522 land, the models over-estimate the seasonal flux of CO_2 to the atmosphere in the tropics, and
523 under estimate it in boreal high latitudes (e.g. Figure 12). In the tropics, we attribute this bias to
524 a combination of the physical model's inability to represent the actual radiative and hydrological
525 cycle in the Amazon (not shown), and the enhanced northward extent of seasonal productivity
526 in the Sahel (Figures 8G-I). In the ocean, both models over estimate surface chlorophyll (Figures
527 3D-F) and the extent of interior suboxia (Figures 4A-C). The relative equatorward restriction of
528 the subtropical gyre oligotrophic region is a cause of concern for the representation of
529 ecological biomes and over estimation of mid-latitude nutrient and oxygen ventilation, both of
530 which are better represented in ESM2G than ESM2M. While not directly connected to the
531 surface biogeochemistry, the oxygen bias has severe implications for the ability to represent

532 hypoxia and denitrification in the tropics (Figure 5B), and to achieve a steady state budget for
533 global alkalinity (Figure 2D) and nitrogen (Figures 2E, 4G-I). Efforts to address these biases are
534 ongoing. Overall, however, the models' very good representation of surface nutrients and
535 $\Delta p\text{CO}_2$ (Figure 3) and interior excess alkalinity (dashed lines in Figure 5), in combination with the
536 general agreement with physical metrics of transport and ventilation discussed in *Part I* (Dunne
537 et al., accepted), give us confidence that the models should have good fidelity in representing
538 ocean carbon uptake and acidification sensitivity under anthropogenic emissions.

539 The primary biogeochemical differences between ESM2M and ESM2G relate to their
540 differing physical representations of thermocline ventilation, and the magnitude of Antarctic
541 Bottom Water (AABW) penetration into the deep Pacific as discussed in *Part I* (Dunne et al.,
542 accepted). In ESM2G, lower thermocline ventilation leads to a lower productivity (Figures 1, 6),
543 higher Southern Ocean and tropical thermocline DIC (Figures 5B, D), and larger northward
544 atmospheric CO_2 transport (Figure 10B) than in ESM2M. In the North Pacific, higher AABW
545 ventilation of the deep North Pacific in ESM2G leads to deficit of DIC relative to ESM2M and
546 observations in deep waters, while higher thermocline ventilation in ESM2M leads to deficit of
547 DIC relative to ESM2G and observations in the upper water column (Figure 5C).

548 In summary, we find ESM2M and ESM2G of similar overall fidelity, both capable of
549 representing the major carbon inventories and fluxes in a prognostic earth system context. The
550 models are capable of simulating realistic levels of biogeochemical function (Figure 1) and
551 global atmospheric CO_2 variability (Figures 11, 12) without significant drift (Figure 2).
552 Regionally, the models are capable of representing factors controlling productivity and net CO_2

553 exchanges between the atmosphere and both land and ocean (Figures 9, 10), though regional
554 biases in variability do exist. The major advantages of ESM2G over ESM2M are improved
555 representation of the subtropical, oligotrophic gyre structure in general and specifically lack of
556 nutrient oxygen ventilation in the Northeast Pacific. The major advantages of ESM2M over
557 ESM2G are in reduced tropical nutrient trapping and suboxia biases - also due to the enhanced
558 thermocline ventilation in ESM2M. While some ocean interior and sediment calcite drifts
559 continue through our control runs, the surface fluxes and interior budgets for both models are
560 balanced to within a 0.1 PgC a^{-1} tolerance in order to provide a strong signal to noise ratio under
561 conditions of anthropogenic CO_2 emissions with Intergovernmental Panel on Climate Change
562 (IPCC) Fourth Assessment consensus estimate for ocean CO_2 uptake in the 1990s at 2.2 ± 0.4
563 PgC a^{-1} (Denman et al., 2007; Table 7.1 therein). We expect the model differences described
564 here will drive much of the ocean carbon uptake and acidification sensitivity under
565 anthropogenic CO_2 emissions between ESM2M and ESM2G. Such simulations and analyses are
566 ongoing as part of GFDL's contribution to the IPCC Fifth Assessment.

567

568 **Acknowledgements**

569 Discussions with Inez Fung, Scott Doney and Chris Jones helped inform the experimental
570 design of these simulations. Charles Stock and Robbie Toggweiler provided extremely helpful
571 reviews of the early manuscript.

777 Figures:

778 Figure 1: Global carbon cycle schematic comparison to estimate by Siegenthaler and Sarmiento
779 (1993) with ocean additions from IPCC; Sabine et al., 2004).

780 Figure 2: Globally averaged time series CO₂ fluxes across the atmosphere-land and atmosphere-
781 ocean interface. The initial conditions (t=0) are taken from prior atmosphere-only and ocean-
782 only integrations and radiative forcing is held constant at 1860 values (see Initialization section
783 for more details). Red lines indicate value from ESM2M, green ESM2G. (A) Annual Air-Sea CO₂
784 flux into ocean in units of PgC/yr. (B) Integrated Air-Sea CO₂ flux into ocean in PgC. (C) Ocean DIC
785 Inventory in units of Eg C. (D) Ocean ALK Inventory in units of EgC equivalent units. (E) Ocean
786 NO₃ Inventory in units of PgN.

787 Figure 3: Sea surface nitrate (NO₃; top row; μM), chlorophyll (Chl.; upper middle row; μg kg⁻¹),
788 air-sea carbon dioxide gas disequilibrium (ΔpCO₂; ppm; lower middle row), and phosphate (PO₄;
789 bottom row; μg kg⁻¹). In each case, the left column is an observational estimate while middle
790 (ESM2M) and right (ESM2G) columns are the model values. NO₃ and PO₄ observations are from
791 the World Ocean Atlas 2009 (Garcia et al., 2010b;
792 http://www.nodc.noaa.gov/OC5/WOA09/pr_woa09.html), SeaWiFS chlorophyll from monthly
793 mapped level-3 concentration data for 1998-2007 (Reprocessing 2009;
794 <http://oceandata.sci.gsfc.nasa.gov>), and ΔpCO₂ from the 2006a reprocessing of Takahashi et al
795 (2009). On the model maps are plotted the bias, correlation coefficient and standard error
796 between the model and observationally based fields.

797 Figure 4: maps of ocean 500 m dissolved oxygen (O_2 ; top row; μM), phosphate (PO_4 ; middle
798 row; μM) and nitrate (NO_3 ; bottom row; μM). In each case, the left column is an observational
799 estimate while middle (ESM2M) and right (ESM2G) columns are the model derived values.
800 Observations are from the World Ocean Atlas 2009 (Garcia et al., 2010a; Garcia et al., 2010b;
801 http://www.nodc.noaa.gov/OC5/WOA09/pr_woa09.html). On the model maps are plotted the
802 bias, correlation coefficient and standard error between the model and observationally based
803 fields.

804 Figure 5: Average vertical profiles of dissolved inorganic carbon (DIC; solid) and excess alkalinity
805 (ALK-DIC; dash) in $\mu\text{mol kg}^{-1}$ for the (A) North Atlantic, (B) Tropics, (C) North Pacific and (D)
806 Southern Ocean for observations corrected to preindustrial values (Key et al., 2004; black),
807 ESM2M (red) and ESM2G (green).

808 Figure 6: Maps of vertically integrated total primary productivity (A-C; $\text{mol C m}^{-2} \text{a}^{-1}$), primary
809 productivity from large phytoplankton alone (D-F; $\text{mol C m}^{-2} \text{a}^{-1}$) and nitrogen fixation rates (G-I;
810 $\text{mol N m}^{-2} \text{a}^{-1}$) in the upper 100 m from ESM2M (A, D, G), ESM2G (B, E, H) and the difference (C,
811 F, I).

812 Figure 7: Zonal integral comparison of various metric of the biological (A; $\text{PgC a}^{-1} \text{deg}^{-1}$) and
813 mineral (B; $\text{PgC a}^{-1} \text{deg}^{-1}$) pumps in the upper 100 m for ESM2M (solid) and ESM2G (dashed).

814 Figure 8: Maps of species type (A-C), above-ground biomass (D-F; kgC m^{-2}), and climatological
815 maximum (G-I) and minimum (J-L) full spectrum Normalized Difference Vegetation Index (NDVI),
816 and. In each case, the left column is an observational estimate while middle (ESM2M) and right
817 (ESM2G) columns are the model derived values. Observations for vegetation type and biomass

818 are from Gibbs (2006) based on Olson et al. (1985) climate types obtained from the Carbon
819 Dioxide Information Center, Oak Ridge National Laboratory, Oak Ridge, Tennessee
820 (<http://cdiac.ornl.gov/ftp/ndp017>). NDVI observations are from Moderate Resolution Imaging
821 Spectroradiometer (MODIS) data.

822 Figure 9: Maps of ESM2M (A, C, E, G) and ESM2G (B, D, F, H) CO₂ flux mean (A, B; mol m⁻² a⁻¹),
823 variability as the standard deviation of monthly mean values (C, D; mol m⁻² a⁻¹), percentage of
824 that variability that is associated with the seasonal cycle rather than interannual modes (E, F;
825 %), and correlations of CO₂ flux variability with surface temperature.

826 Figure 10: Zonally integrated air-sea flux (A) of heat downward (dash; PW deg⁻¹) and CO₂
827 upward (solid; PgC a⁻¹ deg⁻¹), and implied ocean transport (B) of heat northward (dash; PW) of
828 CO₂ southward (solid; PgC a⁻¹) for ESM2M (red) and ESM2G (green).

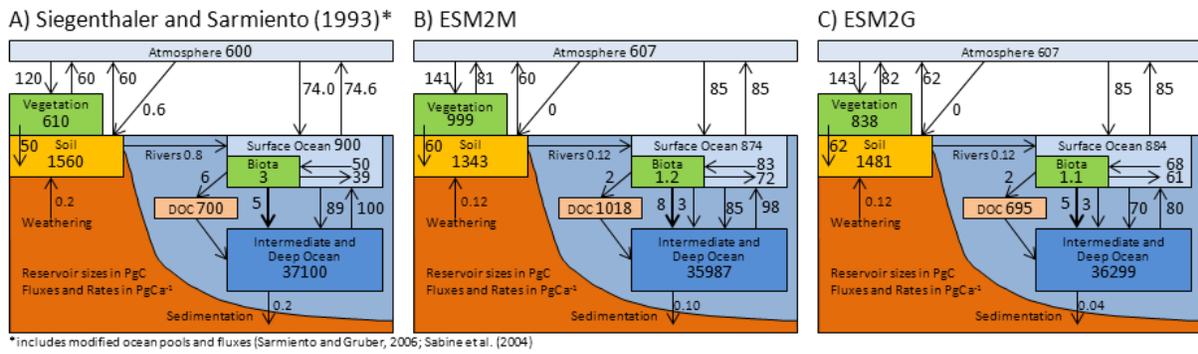

829 Figure 11: Maps of long term average surface atmospheric CO₂ anomalies from the global mean
830 (ppm; A, B), maps of squared correlation coefficient with the temporal variability in the annual
831 global average (C, D) and plots of the variability of annual average CO₂ (E, F) at Greenland
832 (black) and Antarctica (blue) for ESM2M (A, C, E) and ESM2G (B, D, F).

833 Figure 12: Amplitude of the seasonal cycle in CO₂ over marine stations compared to
834 observations, along with insets of the CO₂ wavelet spectra compared to observations from long
835 term monitoring stations at Barrow, Mauna Loa, and the South Pole. Note differing scale of
836 Barrow to the others. Data courtesy of NOAA's Global Monitoring Division's Carbon Cycle
837 Greenhouse Gases Group (<http://www.esrl.noaa.gov/gmd/ccgg/index.html>).

838

839 Figure 1:

840

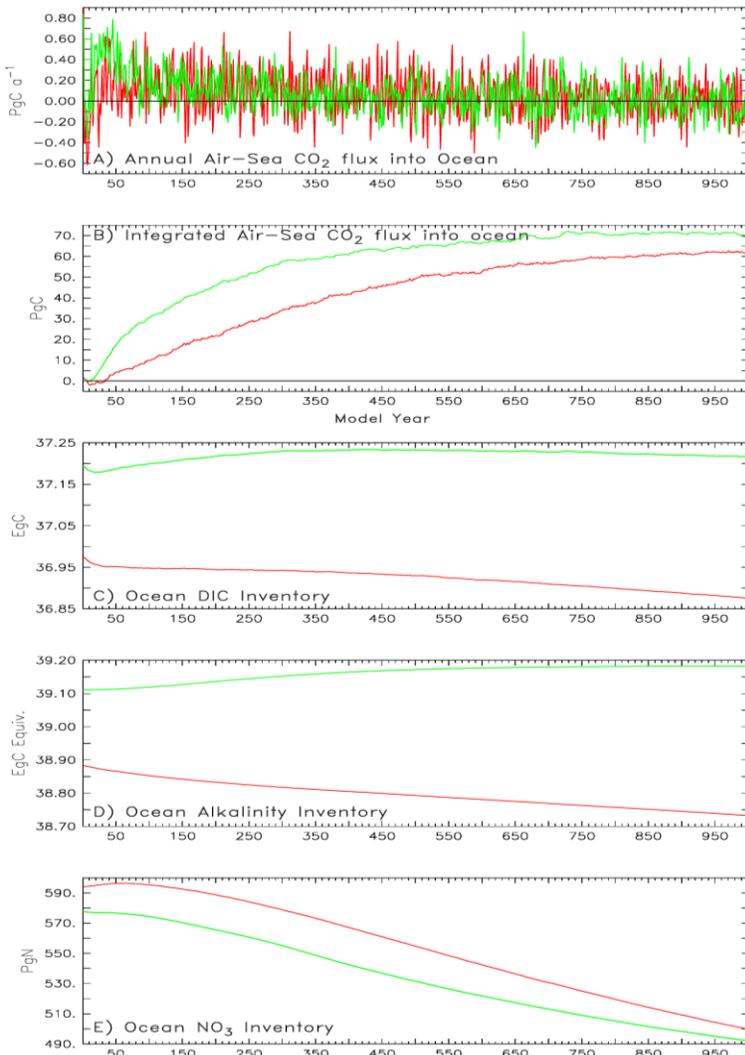

841

842 Figure 1: Global carbon cycle schematic comparison to estimate by Siegenthaler and Sarmiento

843 (1993) with ocean additions from IPCC; Sabine et al., 2004).

844

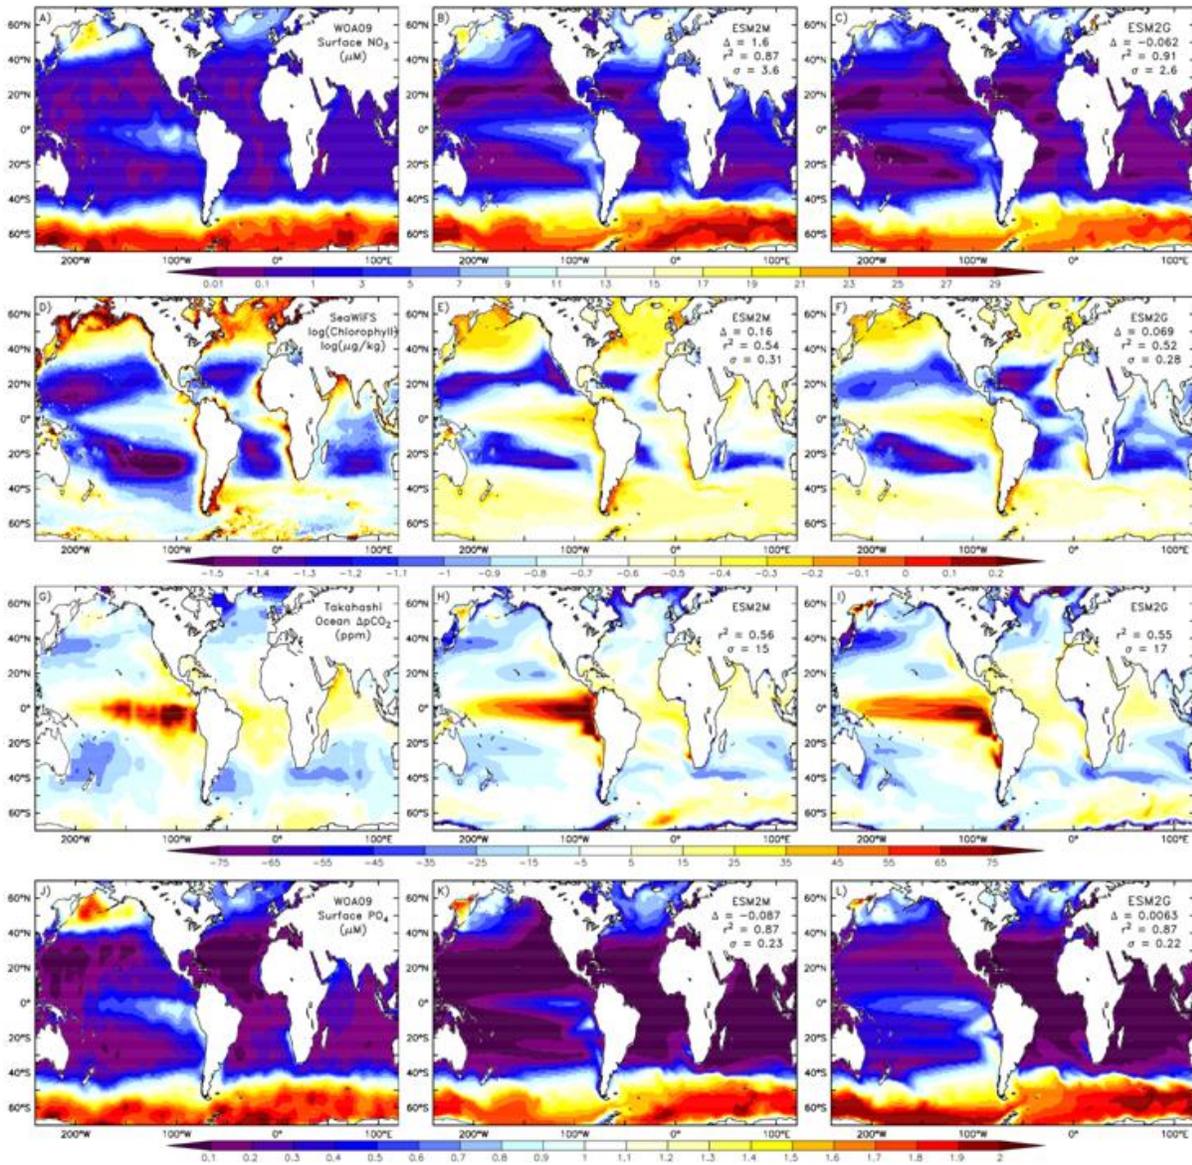

845 Figure 2:

846

847 Figure 2: Globally averaged time series CO₂ fluxes across the atmosphere-land and atmosphere-
848 ocean interface. The initial conditions (t=0) are taken from prior atmosphere-only and ocean-
849 only integrations and radiative forcing is held constant at 1860 values (see Initialization section
850 for more details). Red lines indicate value from ESM2M, green ESM2G. (A) Annual Air-Sea CO₂
851 flux into ocean in units of PgC/yr. (B) Integrated Air-Sea CO₂ flux into ocean in PgC. (C) Ocean DIC
852 Inventory in units of Eg C. (D) Ocean ALK Inventory in units of EgC equivalent units. (E) Ocean
853 NO₃ Inventory in units of PgN.

854 Figure 3:

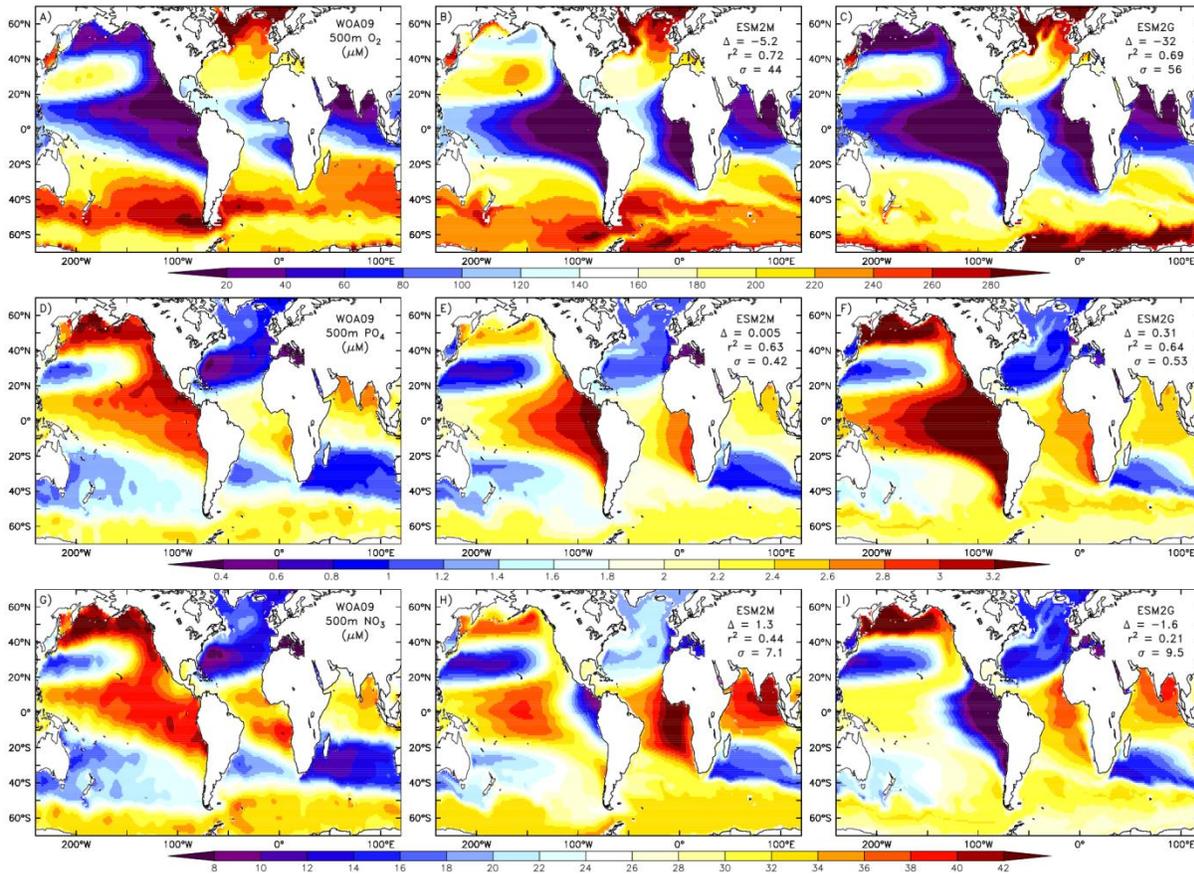

855

856 Figure 3: Sea surface nitrate (NO_3 ; top row; μM), chlorophyll (Chl.; upper middle row; $\mu\text{g kg}^{-1}$),
857 air-sea carbon dioxide gas disequilibrium (ΔpCO_2 ; ppm; lower middle row), and phosphate (PO_4 ;
858 bottom row; $\mu\text{g kg}^{-1}$). In each case, the left column is an observational estimate while middle
859 (ESM2M) and right (ESM2G) columns are the model values. NO_3 and PO_4 observations are from
860 the World Ocean Atlas 2009 (Garcia et al., 2010b;

861 http://www.nodc.noaa.gov/OC5/WOA09/pr_woa09.html), SeaWiFS chlorophyll from monthly
862 mapped level-3 concentration data for 1998-2007 (Reprocessing 2009;
863 <http://oceandata.sci.gsfc.nasa.gov>), and $\Delta p\text{CO}_2$ from the 2006a reprocessing of Takahashi et al
864 (2009). On the model maps are plotted the bias, correlation coefficient and standard error
865 between the model and observationally based fields.

866

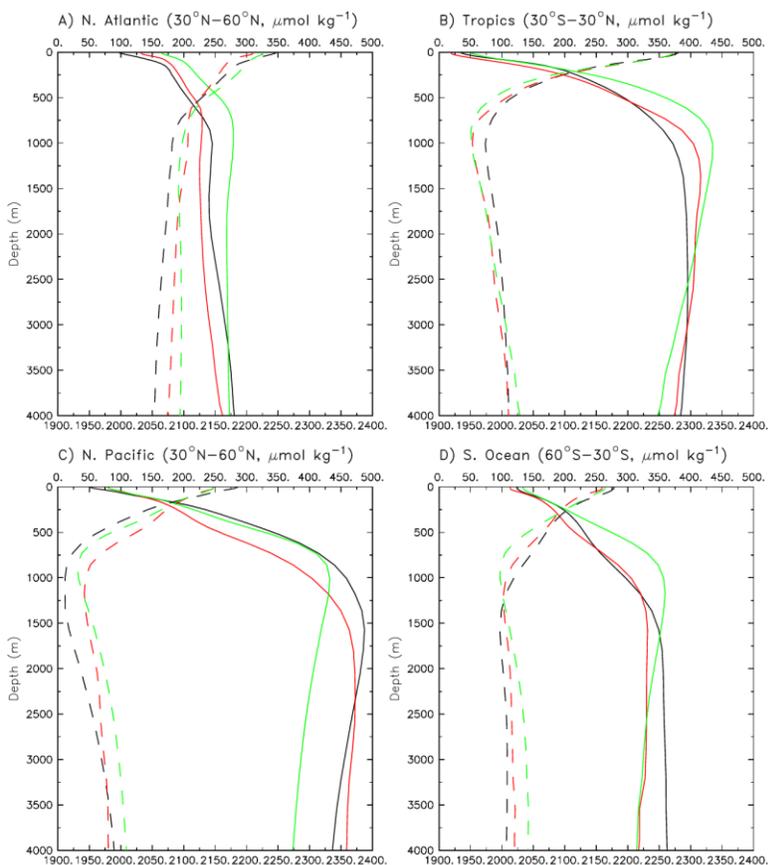

867 Figure 4:

868

869 Figure 4: maps of ocean 500 m dissolved oxygen (O_2 ; top row; μM), phosphate (PO_4 ; middle
870 row; μM) and nitrate (NO_3 ; bottom row; μM). In each case, the left column is an observational
871 estimate while middle (ESM2M) and right (ESM2G) columns are the model derived values.
872 Observations are from the World Ocean Atlas 2009 (Garcia et al., 2010a; Garcia et al., 2010b;
873 http://www.nodc.noaa.gov/OC5/WOA09/pr_woa09.html). On the model maps are plotted the
874 bias, correlation coefficient and standard error between the model and observationally based
875 fields.

876 Figure 5:

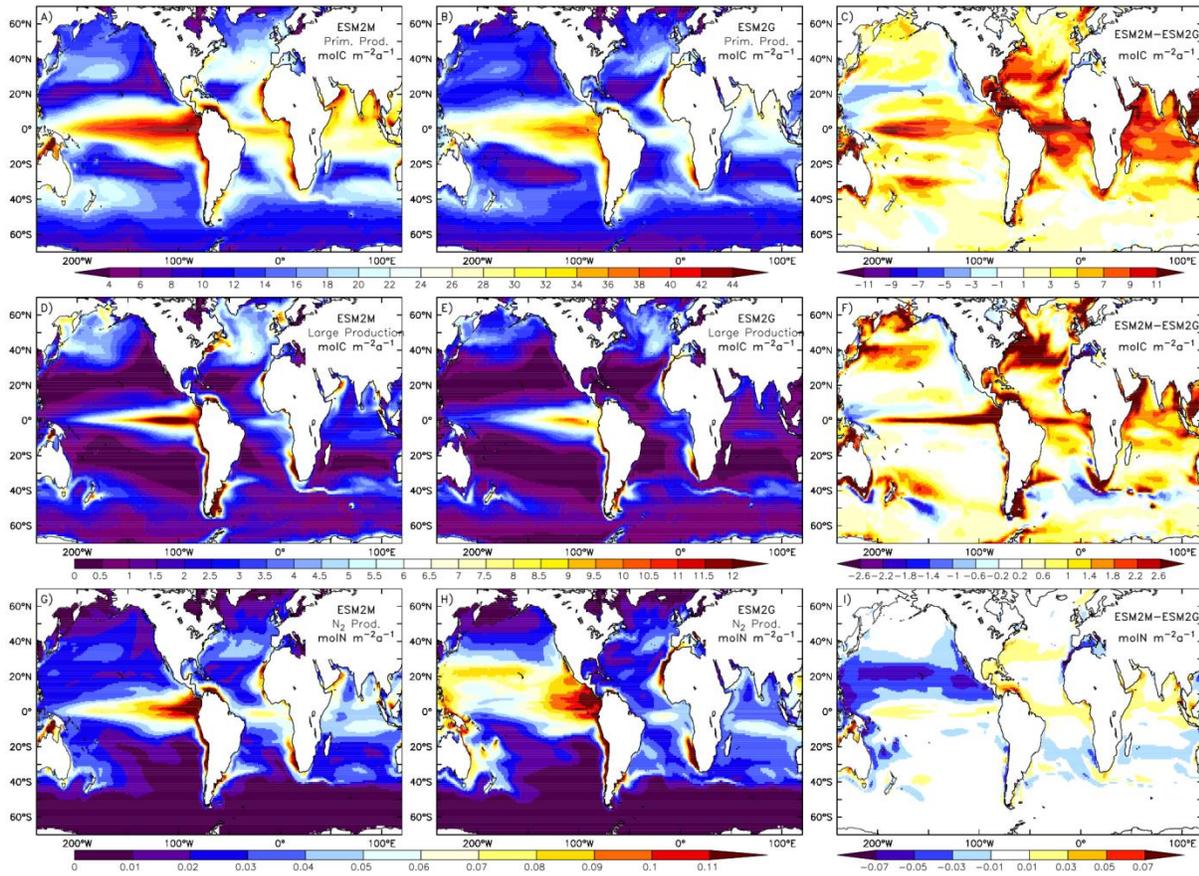

877

878 Figure 5: Average vertical profiles of dissolved inorganic carbon (DIC; solid) and excess alkalinity
879 (ALK-DIC; dash) in $\mu\text{mol kg}^{-1}$ for the (A) North Atlantic, (B) Tropics, (C) North Pacific and (D)
880 Southern Ocean for observations corrected to preindustrial values (Key et al., 2004; black),
881 ESM2M (red) and ESM2G (green).

882

883 Figure 6:

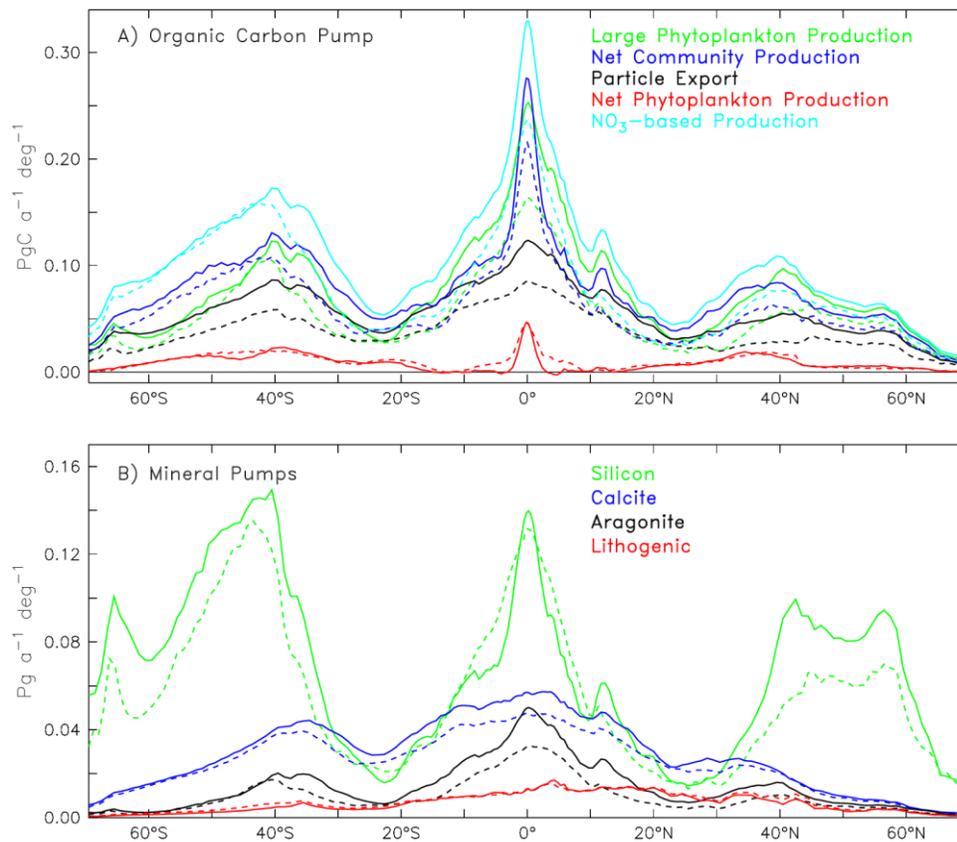

884

885 Figure 6: Maps of vertically integrated total primary productivity (A-C; $\text{mol C m}^{-2} \text{a}^{-1}$), primary
886 productivity from large phytoplankton alone (D-F; $\text{mol C m}^{-2} \text{a}^{-1}$) and nitrogen fixation rates (G-I;
887 $\text{mol N m}^{-2} \text{a}^{-1}$) in the upper 100 m from ESM2M (A, D, G), ESM2G (B, E, H) and the difference (C,
888 F, I).

889

890

891 Figure 7:

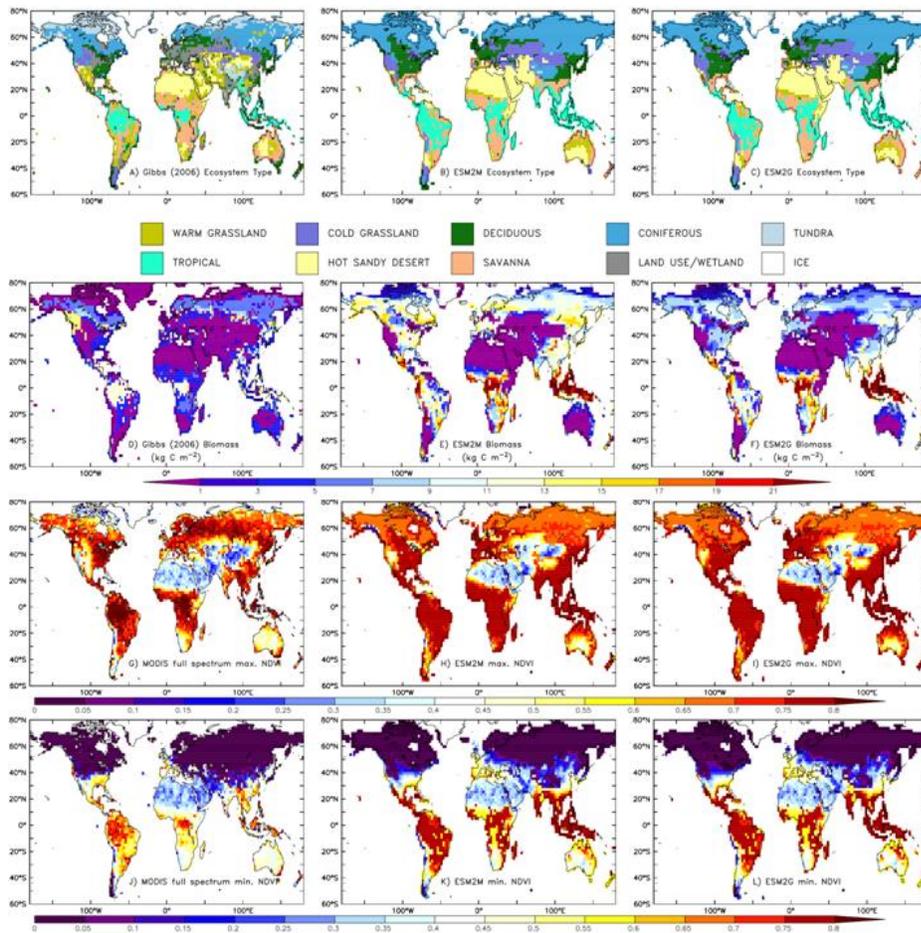

892

893 Figure 7: Zonal integral comparison of various metric of the biological (A; $\text{PgC a}^{-1} \text{deg}^{-1}$) and
894 mineral (B; $\text{PgC a}^{-1} \text{deg}^{-1}$) pumps in the upper 100 m for ESM2M (solid) and ESM2G (dashed).

895

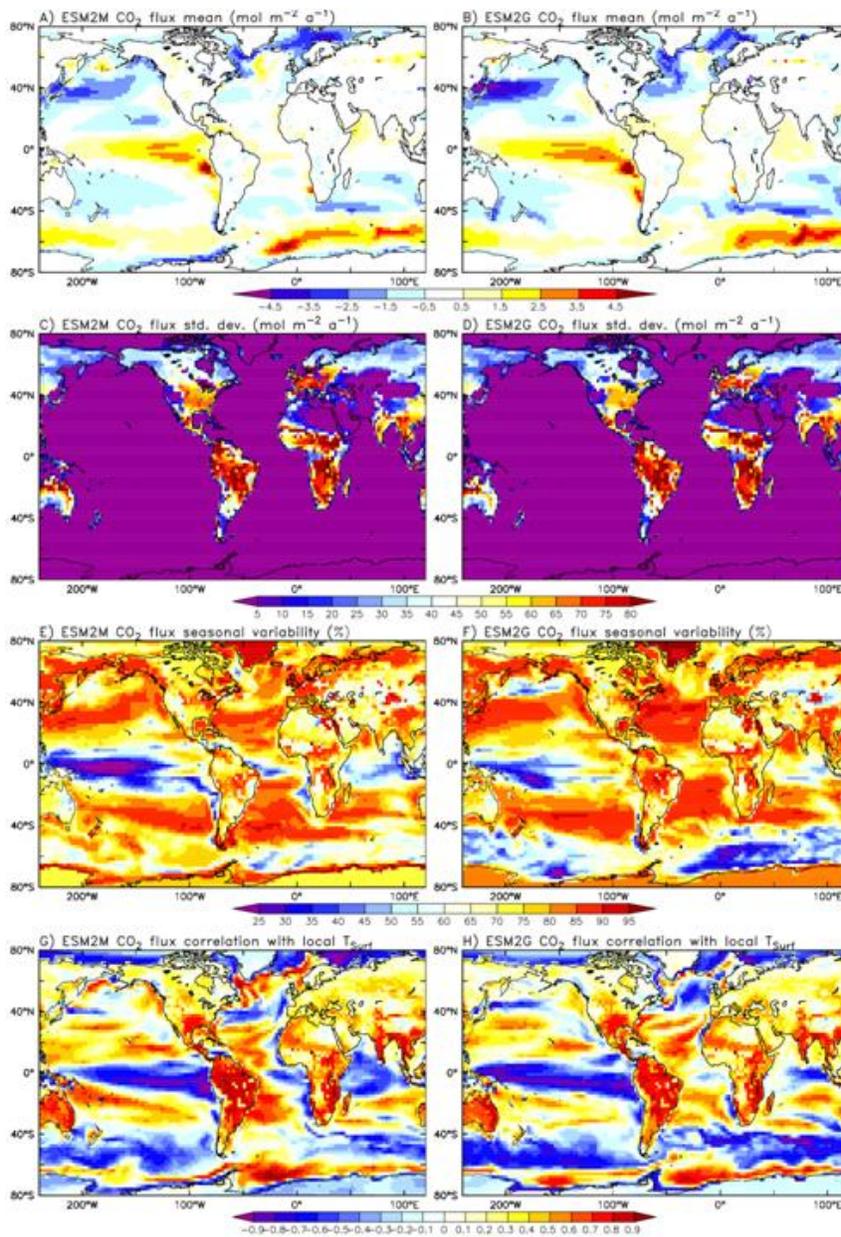

896 Figure 8:

897

898 Figure 8: Maps of species type (A-C), above-ground biomass (D-F; kgC m⁻²), and climatological
899 maximum (G-I) and minimum (J-L) full spectrum Normalized Difference Vegetation Index (NDVI),
900 and. In each case, the left column is an observational estimate while middle (ESM2M) and right
901 (ESM2G) columns are the model derived values. Observations for vegetation type and biomass
902 are from Gibbs (2006) based on Olson et al. (1985) climate types obtained from the Carbon
903 Dioxide Information Center, Oak Ridge National Laboratory, Oak Ridge, Tennessee
904 (<http://cdiac.ornl.gov/ftp/ndp017>). NDVI observations are from Moderate Resolution Imaging
905 Spectroradiometer (MODIS) data.

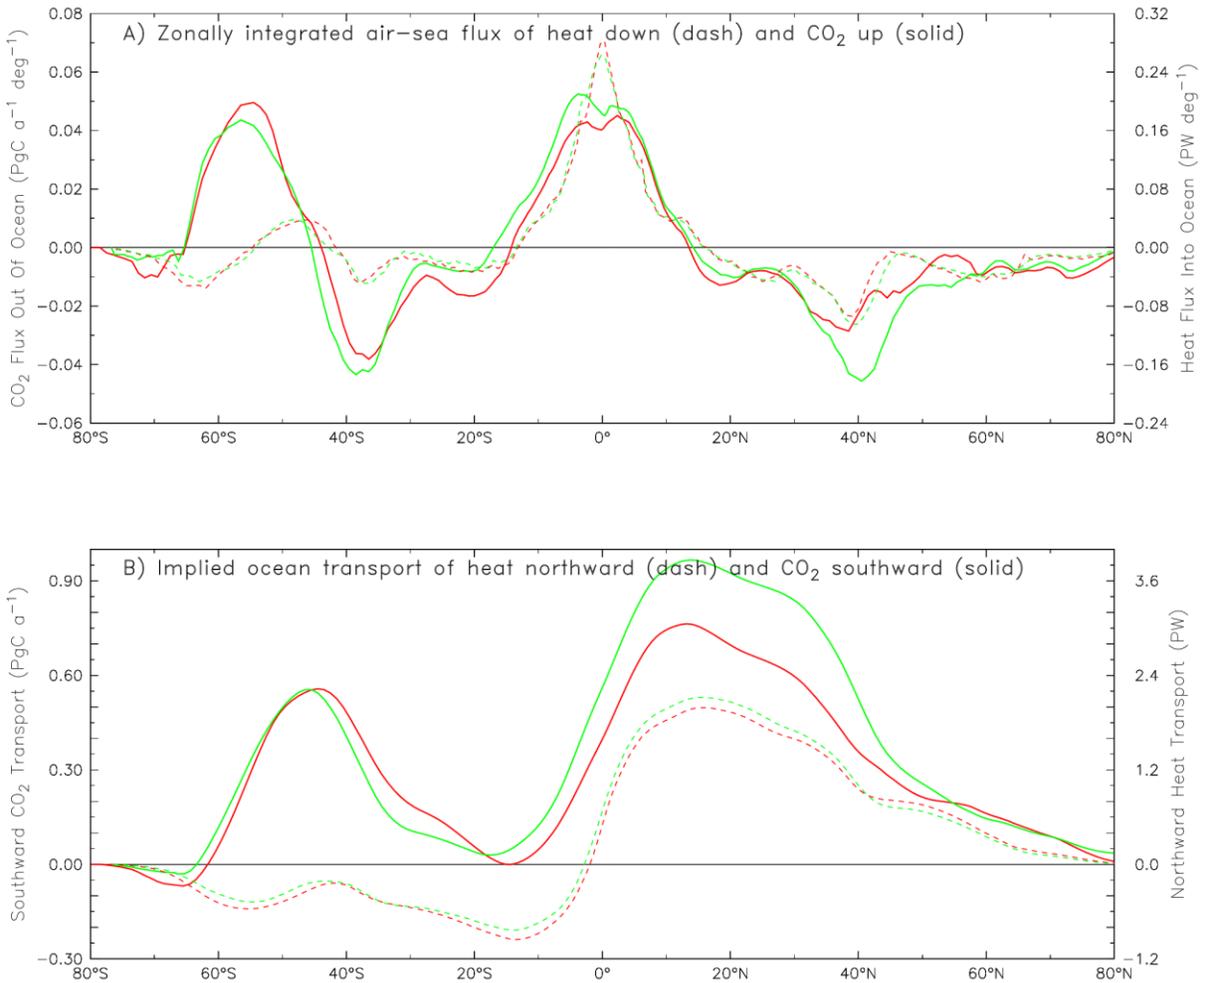

906 Figure 9:

907

908 Figure 9: Maps of ESM2M (A, C, E, G) and ESM2G (B, D, F, H) CO₂ flux mean (A, B; mol m⁻² a⁻¹),
909 variability as the standard deviation of monthly mean values (C, D; mol m⁻² a⁻¹), percentage of
910 that variability that is associated with the seasonal cycle rather than interannual modes (E, F;
911 %), and correlations of CO₂ flux variability with surface temperature.

912 Figure 10:

913

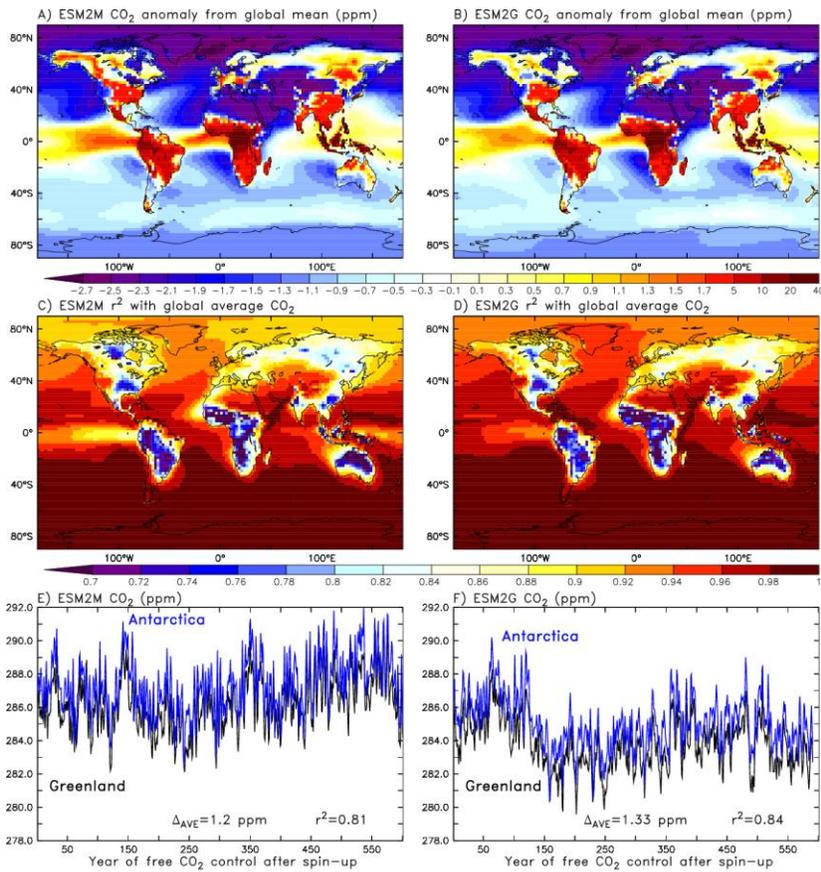

914 Figure 10: Zonally integrated air-sea flux (A) of heat downward (dash; PW deg⁻¹) and CO₂

915 upward (solid; PgC a⁻¹ deg⁻¹), and implied ocean transport (B) of heat northward (dash; PW) of

916 CO₂ southward (solid; PgC a⁻¹) for ESM2M (red) and ESM2G (green).

917

918 Figure 11:

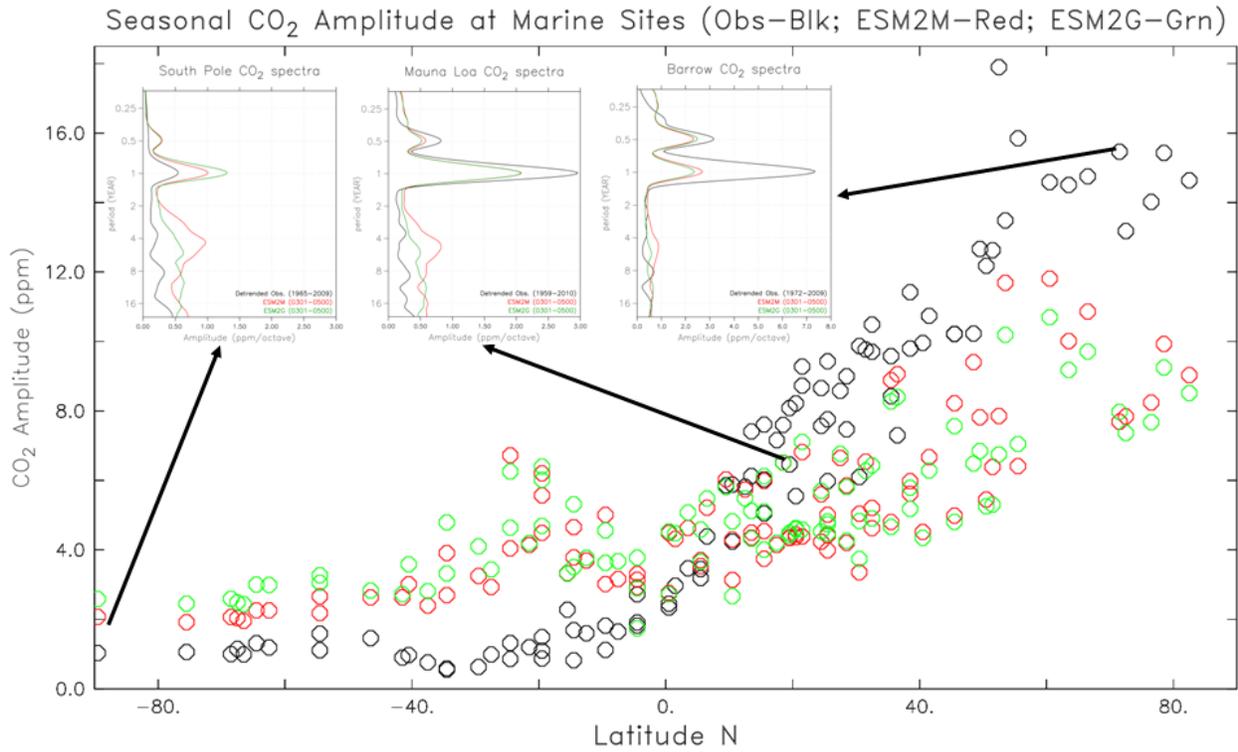

919

920 Figure 11: Maps of long term average surface atmospheric CO₂ anomalies from the global mean
921 (ppm; A, B), maps of squared correlation coefficient with the temporal variability in the annual
922 global average (C, D) and plots of the variability of annual average CO₂ (E, F) at Greenland
923 (black) and Antarctica (blue) for ESM2M (A, C, E) and ESM2G (B, D, F).

924

925 Figure 12:

926

927 Figure 12: Amplitude of the seasonal cycle in CO₂ over marine stations compared to
928 observations, along with insets of the CO₂ wavelet spectra compared to observations from long
929 term monitoring stations at Barrow, Mauna Loa, and the South Pole. Note differing scale of
930 Barrow to the others. Data courtesy of NOAA's Global Monitoring Division's Carbon Cycle
931 Greenhouse Gases Group (<http://www.esrl.noaa.gov/gmd/ccgg/index.html>).
